Comments on Notice of Proposed Rulemaking of the FCC #96-182, CC Docket no. 96-98

by

Prof. Nicholas Economides

This comment is mainly on interconnection pricing issues in a network of interconnected networks. It consists of a short summary and three attached Appendices. Appendix A consists of Nicholas Economides and Lawrence J. White, "Access and Interconnection Pricing: How Efficient is the Efficient Component Pricing Rule?," *Antitrust Bulletin* (Fall 1995). Appendix B consists of Nicholas Economides and Lawrence J. White, "The Inefficiency of the ECPR yet Again: A Reply to Larson," Discussion Paper 96-07, Department of Economics, Stern School of Business, forthcoming *Antitrust Bulletin* (1996). Appendix C consists of "Principles of Interconnection: A Response to 'Regulation of Access to Vertically-Integrated Natural Monopolies'" submitted to the New Zealand Ministry of Commerce. Appendix D is my C V.

The Telecommunications Act of 1996 (1996 Act) establishes that rates for interconnection and network elements shall be "based on the cost (determined without reference to a rate of return or other rate-based proceeding," be "non-discriminatory," and that they "may include a reasonable profit".¹

¹ NPRM 96-182 §123, 1996 Act sec. 101, § 252(d)(1)

1. **Appropriate Pricing of Interconnected Elements**

The appropriate price for interconnected network elements and services is forward-looking long run incremental economic cost, often referred to as total service long run incremental cost (TSLRIC). This is the sum of minimized costs paid to all the factors of production required to supply the network component. TSLRIC has the following features:

1. It is a forward-looking economic cost. That is, it reflects the costs of supplying network component or service using present day technology. It may differ significantly from historical costs, since the technology has evolved rapidly in the telecommunications sector. Forward-looking cost is the current opportunity cost of resources needed to provide the network element. In terms of present day opportunity cost, historical costs are irrelevant.
2. It is the least cost to provide the service, i.e., it is minimized. Thus, the various factors of production (such as plant size, network architecture and structure, labor, land use., etc.) have been optimized so as to minimize cost.
3. It is a long run cost. Thus, it reflects full optimization of all factors of production, including factors that are not variable in the short run.
4. It is an incremental cost. Thus, it reflects the additional costs to provide only the demanded element(s) by an interconnecting network, keeping quantities of other goods constant.
5. It excludes monopoly rents from network element pricing. This is discussed in more detail below under the heading “inappropriateness of the ECPR as pricing principle”.
6. It excludes cross subsidies of any kind.
7. In general, it differs depending on the geographical region.

2. **Inappropriateness of the ECPR as a Pricing Principle**

The NPRM 96-182 §148 tentatively concludes that the "Efficient Component Pricing Rule" (ECPR) is inconsistent with section §252(d)(1) of the 1996 Act. I concur. If applied under the current circumstances, the ECPR would compensate an incumbent provider of a bottleneck facility with its full opportunity cost, including monopoly profits. Thus, adoption of the ECPR, would result in high prices for bottleneck facilities, and for services that use these bottleneck facilities, thereby creating or preserving an allocative inefficiency.² Similarly, other rules that may include monopoly rents in the price of network elements are also inappropriate.

The ECPR was motivated by a desire to limit entry by inefficient firms in markets that are complementary to the bottleneck. However, Economides and White (1995, 1996) and Economides (1995) show that entry even by inefficient firms in such complementary markets can be socially desirable because it leads to lower prices. In general, entry in the complementary market by a slightly inefficient competitor will *always* lead to lower prices and higher social welfare if ECPR is not applied.

When the technology of production involves increasing returns to scale, a monopolist may use the ECPR rule to exclude or marginalize a more efficient rival in the complementary market. The monopolist uses the ECPR to establish high interconnection charges that result in a restriction

² See Economides and White, "Access and Interconnection Pricing: How Efficient is the Efficient Component Pricing Rule?," *Antitrust Bulletin* (Fall 1995), Appendix A; Economides and White, "The Inefficiency of the ECPR yet Again: A Reply to Larson," Discussion Paper 96-07, Dept. of Economics, Stern School of Business, forthcoming *Antitrust Bulletin* (1996), Appendix B; "Principles of Interconnection: A Response to 'Regulation of Access to Vertically-Integrated Natural Monopolies'" (1995) submitted to the New Zealand Ministry of Commerce, Appendix C.

of the scale of operation of the rival in the complementary market. Because of the existence of increasing returns to scale, the rival operates at the high end of its cost curve. The dominant incumbent is able to raise the production costs of its rival through the implementation of the ECPR. Accordingly, the rival is hurt by the ECPR twice: first, because of high interconnection charges; and second, because it is forced to operate at small scale and at high unit cost. Thus, the ECPR can be used to implement a tight profit squeeze on a rival or even to exclude the rival. In this process, consumers are deprived of lower prices that would have resulted from competition if ECPR was not applied.

In the presence of ECPR, the monopolist has an incentive to understate its marginal costs of production of the complementary component (i.e., the service where it faces competition) and then employ the ECPR to levy an exclusionary access charge vis-a-vis its rival. The effects of this strategy are similar to the ones described in the previous paragraph. That is, more efficient rivals are excluded. Even if the monopolist is constrained to earn zero profits in the bottleneck market, if its costs are not perfectly observed, it can claim that some marginal costs of the complementary services are marginal costs of the bottleneck service. Lower marginal costs of the complementary component justify a higher charge under the ECPR. This higher charge will now deter even those rivals which are more efficient than the monopolist in the production of the complementary component.

The ECPR reduces competition in markets that are both vertically related and horizontally related to the bottleneck monopolist. By requiring any interconnecting network to pay high access charges, the ECPR ensures a reduced impact of competition in any market that is vertically related to the bottleneck monopoly (i.e., any market that provides goods or components that are

complementary to the service for the bottleneck monopolist). Accordingly, since long distance providers have to interconnect with the bottleneck monopolist in the local market, the application of the ECPR by the bottleneck monopolist reduces the impact of competition in the long distance market.

A *local* competitor of the bottleneck monopolist is harmed by the application of the ECPR. A competitor of the dominant incumbent monopolist which provides local service in some regions or which provides mobile service (a substitute to fixed local service) requires interconnection to the local network of the monopolist. Since the component of final service provided by the competitor is complementary to the component of the final service provided by the owner of the bottleneck facility, the two firms, monopolist and competitor, are vertically related. At the same time, the competitor may be seeking actively to win subscribers over to its network. It is thus in direct competition with the dominant incumbent monopolist. The ECPR justifies to the monopolist high interconnection charges that lead to a marginalization of the competitor (through a price squeeze). The ECPR therefore reduces horizontal competition.

Therefore, *the ECPR effectively prohibits competition in the bottleneck market*. Often, a bottleneck market is described as a natural monopoly. The ECPR makes the bottleneck market a *legal monopoly*, irrespective of whether or not it is a natural monopoly. When the ECPR is applied, the possibility of competition in the bottleneck market is eliminated. This is because a potential entrant in this market must pay to the dominant incumbent its full opportunity cost. Accordingly, the application of the ECPR rule can lead to horizontal exclusion.

I have a consulting arrangement with AT&T. However, this is an independent submission, is not done on AT&T's behalf, and may not reflect AT&T's position on these matters.

Nicholas Economides

Access and interconnection pricing: how efficient is the “efficient component pricing rule”?

BY NICHOLAS ECONOMIDES* and LAWRENCE J. WHITE*

I. Introduction

The question of how a monopolist owner of a bottleneck facility should set the price for access to the facility by an entrant or rival supplier of a complementary component continues to be an interesting question for theory and policy.¹ This question is often

Clear Communications Ltd*, Privy Council, House of Lords, U.K. (1994), Curtis M. Grimm & Robert G. Harris, *Vertical Foreclosure in the Rail Freight Industry: Economic Analysis and Policy Implications*, 5 ICC PRACT. J. 508 (1983); Henry McFarland, *Railroad*

framed in terms of a regulated monopolist vis-a-vis an entrant or rival in an unregulated complementary activity; but the issue can also arise in the antitrust context of an unregulated "essential facility" monopolist that is vertically integrated into a complementary upstream or downstream activity in which one or more other producers are present (or may enter).²

As technological changes and legal-regulatory changes have created more opportunities for competition in activities that are complementary to a still-regulated bottleneck facility, the policy relevance of the access pricing question has been heightened. Familiar examples include:

Local telephone service entrants who must route calls to and from the customers of the incumbent (bottleneck monopoly) provider through the incumbent's switches.

Long-distance telephone service providers who must access customers via the local (monopoly) switched network; this example extends immediately to other providers of complementary telephone services. In these instances, the local monopolist is usually also an actual or potential provider of the long-distance and other complementary services.

² For recent discussions of the essential facilities doctrine, see Gregory Werden, *The Law and Economics of the Essential Facilities Doctrine*, 32 ST. LOUIS U. L. REV. 432 (1987); James Ratner, *Should There Be an Essential Facilities Doctrine?*, 21 U. C., DAVIS L. REV. 327 (1988); and David Reiffen & Andrew N. Kleit, *Terminal Railroad Revisited: Foreclosure of an Essential Facility or Simply Horizontal Monopoly?*, 33 J. L. & ECON. 419 (1990).

Generators of electricity who wish to sell to ultimate customer-users but who can reach those customers only through a local (monopoly) distribution network (and possibly also a monopoly transmission system); again the local monopoly distributor typically also owns generating facilities.

Sellers of natural gas who similarly wish to sell to ultimate customer-users but who can reach those customers only through monopoly gas transmission pipelines and/or a monopoly local distribution network.

In addition, eased merger standards in some sectors (e.g., railroads) have created local monopoly bottlenecks that generate an access problem for competing firms that provide complementary components or services.

A widely discussed "rule" for the pricing of access to these bottleneck facilities was originally proposed by Baumol³ and has recently been popularized by Baumol and Sidak;⁴ it is frequently described as the "efficient component pricing rule" (ECPR), which is the terminology that we will use in our subsequent discussion. The ECPR states that the appropriate access charge by the bottleneck monopolist to the providers (actual or potential) of a complementary component or service, which the monopolist also produces (and thus the other providers are rivals to the monopolist), is a fee equal to monopolist's opportunity costs of providing the access, *including* any foregone revenues from a concomitant reduction in the monopolist's sales of the complementary component.

The ECPR has a seductive logic: It insures that a rival producer of the complementary component can provide service only if that producer is at least as efficient as the monopolist in the production of the complementary component; i.e., the ECPR insures that production will not be diverted to an inefficient producer.

It is now well established that the ECPR holds as a first-best pricing principle only if a stringent set of assumptions holds:⁵ the

³ See Baumol, *supra* note 1.

⁴ See Baumol & Sidak, *supra* note 1, and BAUMOL & SIDAK, *supra* note 1.

⁵ See Laffont & Tirole, *supra* note 1.

monopolist's price for the complementary service has been based on a marginal-cost pricing rule; the monopolist's and rival producer's components are perfect substitutes; the production technology of the component experiences constant returns to scale; the rival producer has no market power; and the monopolist's marginal cost of production of the component can be accurately observed.

In this article, we will examine the consequences of relaxing some of these assumptions. We focus special attention on the case where the monopolist has been charging a price for the complementary component that is above all relevant marginal costs. As we show, in this case the ECPR's exclusion of inefficient rivals may be socially *harmful*; the market presence of even an inefficient rival could bring net social benefits, by causing the price to fall sufficiently so that the net gain to consumers (the reduction in the deadweight loss "triangle") would exceed the inefficiency costs of the rival's production.

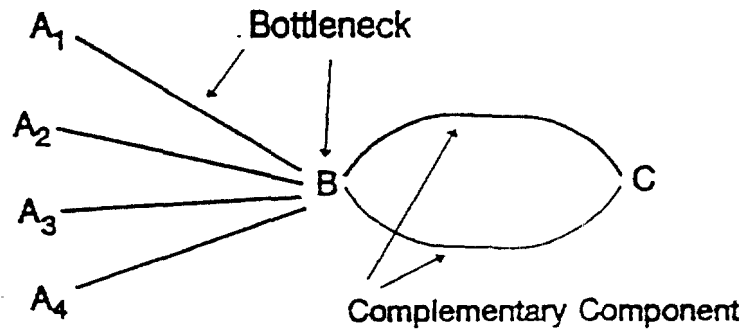

To help readers with the analysis that follows, we offer figure 1 as a schematic of the framework that we are presenting. We describe our framework in terms of telephone services (but the other examples mentioned above are easily applied): The monopolist owns the switch at location B and provides local telephone service between and among customers at points A₁, A₂, A₃, etc. All of the local customers must use the monopolist's switch to complete (connect) their local calls and to gain access to other (complementary) services, such as long distance.

The same firm that provides the monopoly local service also provides service from points A₁, A₂, A₃, etc., through switch B to point C. This service could be "long distance"; or it could be additional "local" service to additional customers; or it could be some other complementary service (e.g., access to an information database) that requires the use of switch B. We will describe this ABC (or CBA⁶) service simply as "through service." There is at

⁶ For a discussion of one-way networks and two-way networks, see Nicholas Economides & Lawrence J. White, *Networks and Compatibility: Implications for Antitrust*, 38 EURO. ECON. REV. 651 (1994). In two-way networks, such as telephone or rail systems, ABC and CBA are distinct

Figure 1

Interconnection to a Bottleneck. (The links owned by the monopolist are drawn in bold)

least one other potential or actual provider of the service to point C. This rival requires access to (through) the switch in order to provide the A_1 , A_2 , A_3 , etc., customers with the “through” service ABC (and CBA). We assume, however, that the rival owns only facilities between BC, while the monopolist owns the switch B as well as its own facilities between BC (drawn in bold) and the links A_1B , A_2B , etc. In the language of the ECPR, the switch B is the monopoly bottleneck⁷ and segment BC is the complementary component.

The early sections of the article will assume the following:

The monopolist and the rival offer identical service over segment BC.

Service between B and C has value only as part of the through service ABC or CBA.

Constant returns to scale production technology applies to the production of service between B and C.⁸

goods or services. In a one-way network (such as an electricity grid), only one of these combinations is meaningful.

⁷ The segments *between* B and A_1 , A_2 , A_3 , etc., may or may not also be part of the monopoly bottleneck.

⁸ We will make the standard economics assumption that normal, competitive profit levels will be a component of the cost concepts discussed later in the article.

The monopolist is able to charge prices for local service to its local customers that are sufficient to cover all of its costs of providing that local service (i.e., sufficient to cover the costs of providing links AB and the costs of the switch).

The price of the through service ABC (and CBA) is not subject to direct price regulation.

The consumer demands for local service and through service exhibit normal properties; e.g., the prices that consumers are willing to pay are indicative of the welfare or satisfaction that they receive from the services; at lower prices consumers want to buy more of the services, etc.

In later sections of the article we will explore the consequences of modifying some of these assumptions.

The remainder of this article will proceed as follows: section II will lay out the structure of the basic ECPR and explore its logic. Section III will examine the consequences of the monopolist's price embodying a monopoly overcharge. Section IV will analyze the consequences of the components' not being perfect substitutes. Section V discusses the case when economies of scale are present. And section VI will offer a brief conclusion.

II. The logic of the efficient component pricing rule

The logic of the ECPR is readily demonstrated through a simple numerical example:

Suppose that the monopolist charges a price of \$0.10 for through service ABC (or CBA). Suppose further that the monopolist's marginal costs of providing this service are \$0.02 for segment BC and \$0.05 for segment AB (including the relevant marginal costs of the switch B). *The ECPR simply states that the appropriate price or fee for the monopolist to charge to the rival for access to switch B (and for providing the connecting service AB) is \$0.08:* The \$0.05 of marginal costs relevant to segment AB *plus* the foregone net revenue of \$0.03 that the monopolist loses when the rival provides the through service in lieu of the monopolist.

If the rival is being charged a fee of \$0.08 for access, and the monopolist is charging \$0.10 as its price to customers for through service, then the rival will be able to offer through service without incurring losses only if its marginal costs for segment BC are at or below \$0.02—i.e., at or below the marginal costs (over BC) of the monopolist.

Thus, the ECPR insures that the rival enters and produces in the market only if its costs are no greater than those of the monopolist; inefficient diversion of production away from the monopolist will not occur as a consequence of the presence of the rival in the market. Further, if all of the conditions mentioned in the Introduction (including pricing by the monopolist at marginal cost) are satisfied, the ECPR will provide global efficiency.

III. The monopolist initially has market power in the complementary component

The previous section made no explicit assumption as to the basis for the monopolist's price for the through service. We now explicitly assume that in the absence of the rival the monopolist is able to charge the full profit-maximizing monopoly price for the through service.⁹ In turn, this maximizing behavior implies that the monopolist's markup over marginal costs is directly related to those marginal costs and to the elasticity of demand for the service.

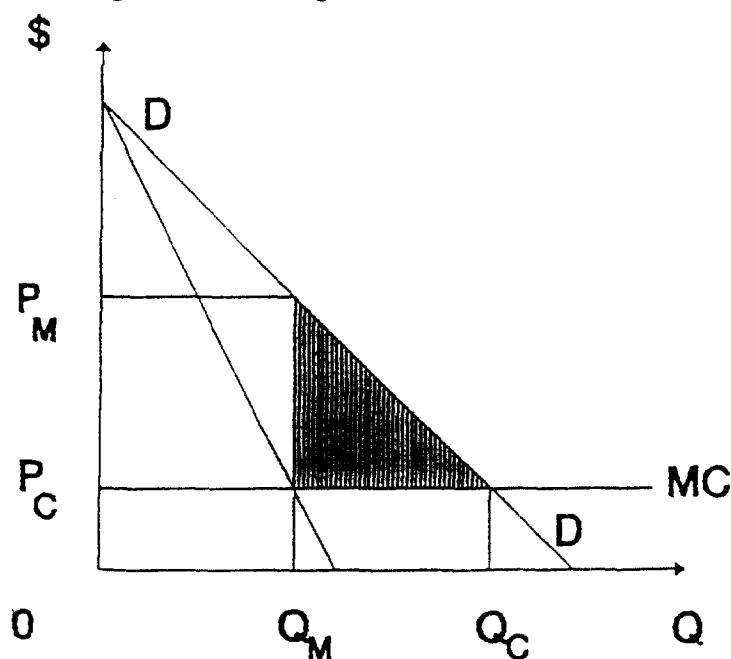

This monopoly outcome can be portrayed in a familiar geometric diagram, provided in figure 2. With demand curve (DD) for through service and constant marginal costs (MC) for the monopo-

⁹ Baumol & Sidak, *supra* note 1, and BAUMOL & SIDAK, *supra* note 1, briefly acknowledge the possibility that the monopolist's price for the complementary component (or, in our case, through service) might reflect market power and not be based on a marginal-cost pricing rule, and they acknowledge that this possibility would mean that the optimal properties of the ECPR would not hold; but they nevertheless devote virtually all of their analysis and discussion to the case where market power is absent. Kahn & Taylor, *supra* note 1, note this brief acknowledgement and the possibilities that might follow from market power, but they do not fully pursue the point.

list, the profit-maximizing monopolist would charge a price of P_M and produce a quantity Q_M . (This can be compared to the price P_C and quantity Q_C that would be yielded by a marginal-cost pricing regime.) The monopolist's markup over marginal costs is the vertical distance between P_M and MC .

Figure 2

Monopoly Pricing and Deadweight Loss

The ECPR described in the previous section would prescribe that the monopolist's markup or overcharge be a component of the access fee. Thus, the ECPR would deter inefficient rivals (those with marginal costs that are higher than the monopolist's MC) and prevent inefficient production. *But the ECPR also protects the monopolist from any competitive challenge by these rivals and thus protects the monopolist's profits; and the ECPR preserves the allocative or consumption inefficiency that results from the monopolist's excessively high price for through service.* The social loss of the protected monopoly is usually calculated as the "deadweight loss triangle" (DWL) shown as the shaded area in figure 2: The loss of consumers' surplus by demanders who are shut out of the market by the monopolist's high price.

It is easy to see that, if the monopolist has market power in the market for the complementary component, the ECPR is the monopolist's profit-maximizing access fee when the rival is less efficient than the monopolist, since the ECPR precludes entry and allows the monopolist to continue to reap its full monopoly rents.¹⁰

A. Production by a less efficient rival could yield net social gains

If the monopolist were required (e.g., by regulation) to levy a lower access fee, a less efficient rival could begin production. But it is nevertheless possible that social welfare would increase, because the diminished DWL from the lower price that could accompany entry could more than compensate for the social cost of the rival's inefficient production.¹¹ The magnitudes of the price decrease and the rival's inefficiency, and also the fractions of post-entry production that the rival captures, will be crucial to this determination.

1. BERTRAND COMPETITION To show that entry by even an inefficient rival could yield socially beneficial results, we assume that the monopolist is restricted (e.g., by regulation) to levying an access fee that is equal only to the actual marginal costs of access (i.e., the marginal costs of segment AB, including the switch). We further assume that an entrant to segment BC has higher costs than the monopolist by an amount t , where $0 \leq t \leq (P_M - MC)$.

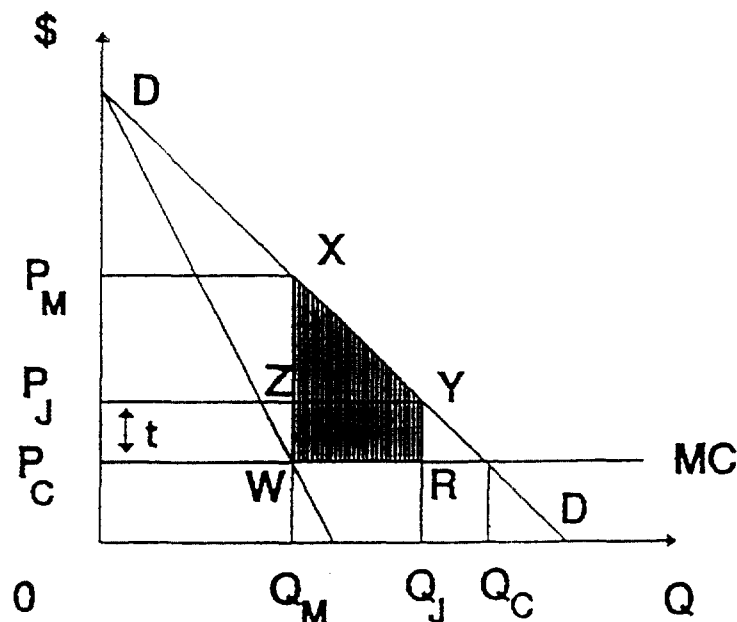

Suppose that in response to the prospect or actuality of entry, the monopolist practices limit pricing: It sets the price (P_J) at which both producers sell at a level that is just equal to the entrant's costs. Under this pricing regime the entrant will capture some share θ ($0 \leq \theta \leq 1.0$) of the joint market sales (Q_J) of through service.

¹⁰ The profit-maximizing access fee when the rival is more efficient than the monopolist is discussed below in the text.

¹¹ The analysis that follows in the text is an adaptation, in reverse form, of the approach of Oliver E. Williamson, *Economics as an Antitrust Defense: The Welfare Tradeoffs*, 58 AM. ECON. REV. 18 (1968).

In the terms of figure 3, consider the change from pure monopoly (point X) to limit pricing (at point Y). The approximate social gain from this change is a combination of a "triangle" gain in consumers' surplus ($\frac{1}{2} \Delta P \cdot \Delta Q = \frac{1}{2}[P_M - P_J] \cdot [Q_J - Q_M]$), represented by area XYZ, and a "rectangle" gain in producers' surplus ($t \cdot \Delta Q = t \cdot [Q_J - Q_M]$), represented by area ZYRW; the combined areas are the trapezoid XYRW. This gain is offset by the production inefficiency: the entrant's cost disadvantage multiplied by the entrant's production volume, or $t\theta Q_J$, which represents some fraction (θ) of the rectangle $P_J Y R P_C$. The net gain can be either positive or negative, depending on the values of t , θ , and the elasticity of demand (e).

Figure 3
Dead Weight Gain and Production Inefficiency

For specified values of θ and e , it is possible to find (solve for) a maximum level of cost disadvantage (t^*) that just eliminates the net social gain.¹² Then, for the specified values of θ and e , entry by a firm with cost disadvantage t , $t < t^*$, will yield a social gain. In table 1 we provide the t^* values associated with a range of

¹² Appendix A provides the calculations that yield t^* .

plausible values for e and for some benchmark values of θ : $\theta = 0$ (the mere threat of entry causes the monopolist to practice limit pricing); $\theta = 0.5$ (a Bertrand equal-sharing of the market between the monopolist and the rival); and $\theta = 1.0$ (the "worst" case, in which the less efficient rival somehow captures the entire market). As can be seen, for these "realistic" elasticity values, a rival may experience a substantial cost disadvantage and still be the vehicle for a net social welfare improvement. These results are even more striking if the rival's cost disadvantage is expressed as a percentage of the monopoly's profit-maximizing price differential (or profit margin).

Table 1

Matrix of t^* Values for Bertrand Competition

θ	Elasticity e		
	2.0	3.0	4.0
0	1.00* (100%)	0.50* (100%)	0.33* (100%)
0.50	0.67 (67%)	0.33 (65%)	0.21 (65%)
1.0	0.50 (50%)	0.24 (47%)	0.15 (46%)

* Profit maximizing monopoly markup over marginal cost (profit margin).

NOTE: The numbers in parentheses represent t^* expressed as a percentage of the maximum monopoly markup.

2. COURNOT DUOPOLY We have thus far performed our analysis on the basis of an assumption of a "tough" pricing environment between the monopolist and the rival: Bertrand-like limit pricing by the monopolist. More accommodating behavior between the monopolist and the rival would yield higher prices for any t by the rival and hence a lesser likelihood of a social welfare gain; at the limit, if both the monopolist and rival sell at the monopoly price (P_M), with the monopolist ceding to the entrant some share θ of the monopoly volume (Q_M), then the outcome yields only the social loss ($t\theta Q_M$) due to the inefficient production of the entrant.

As an example of an intermediate level of pricing toughness, we assume that the competition between the incumbent and the entrant is a-la-Cournot: i.e., each producer adjusts its own produc-

tion quantity on the assumption that the other producer's quantity will remain unchanged. If a linear demand curve is used for illustration, then, similar to our Bertrand demonstration, we can solve for a t^* , such that all $t < t^*$ will yield a net social gain.¹³ For this Cournot conjecture by the producers, the market share of the entrant (θ) is endogenous, with $\theta = 0.31$ (i.e., a market share of 31%) at $t = t^*$ and $\theta = 0.50$ at $t = 0$. Table 2 shows the critical values of t^* for the same "realistic" values of e that were provided in our Bertrand case. As can be seen in a comparison of table 2 with table 1, the t^* values for this Cournot case are smaller than for the Bertrand case, because Cournot competition implies higher prices and a substantial market share for the less efficient rival. Still, again, *entry by a firm with a nontrivial production cost disadvantage relative to the monopolist can result in a net social gain.*

Table 2

Values of t^* for Cournot Competition

Elasticity e		
2.0	3.0	4.0
0.29 (29%)	0.17 (33%)	0.12 (35%)

NOTE: The numbers in parentheses represent t^* expressed as a percentage of the maximum monopoly markup.

We also note that if more than one rival is present in the market, so that there is competition among a number of firms, the equilibrium price is likely to be closer to the Bertrand limit pricing case, and definitely lower than for the Cournot duopoly. Thus, in the presence of more than one rival, the welfare gain from the competition that they bring is more likely to be positive.

3. A SUMMING UP The ECPR's apparent strength—its exclusion of an inefficient rival—may also be its drawback when the monopolist is charging high prices (in excess of all relevant marginal costs) for the complementary component. In that case, the exclusion of the rival also prevents the possibility of a lower price for the complementary component, with its attendant reduc-

¹³ Appendix B shows the steps that are required to solve the Cournot competition problem and generate a solution for t^* .

tion in consumers' deadweight loss; the net social gain from the rival's presence could be positive. The extent of the price decrease, the size of the rival's cost advantage, and the rival's equilibrium market share are the key determinants of whether the rival's presence in the market would be beneficial. In turn, the oligopolistic conjecture held by the two producers and the market elasticity of demand will influence these magnitudes. At one extreme, if the monopolist practices Bertrand-like limit pricing, the presence of a rival with even a substantial cost disadvantage can be socially beneficial. At the other extreme, if the monopolist and the rival jointly maintain the monopolist's previous high price (with the monopolist simply ceding some market share to the rival), then any market presence by a less efficient rival will be socially deleterious. Cournot duopoly yields an equilibrium price that is between these extremes, with an endogenously determined market share for the rival. Even with Cournot duopoly, nontrivial cost inefficiencies by the rival are consistent with a net social gain.

Further reflection on the ECPR reveals both a greater universality to its logic but also a greater universality to the critique that we have just offered.¹⁴ Though the ECPR is usually presented in terms of access to a bottleneck facility, its logic extends to any entry by any rival firm into any market where there is an incumbent. If the sole goal of social policy is to prevent inefficient production by an entrant from displacing more efficient production by the incumbent, then the ECPR principle—the entrant must reimburse incumbent for the latter's opportunity costs, including foregone net revenues—will achieve that goal. But, *if the incumbent is exercising market power, then the use of the ECPR will also protect the incumbent and preserve its market power against the competitive erosion of prices and margins that even less efficient rivals could bring.* If the ECPR is placed in this context, the luster of its rationale tarnishes rapidly.

An "entry tax" that required market entrants generally to reimburse incumbents for their foregone net revenues would quickly

¹⁴ We are grateful to Timothy Brennan for pointing this out to us.

be seen as a protective and anticompetitive device and would likely receive little support from policy-oriented economists, despite any claims that the tax would preclude inefficient production. The ECPR is just this type of entry tax.

B. The ECPR's harm when the rival is more efficient than the monopolist

The previous section only addressed instances where the rival is less efficient than the monopolist in the production of the complementary component. Even in those circumstances, as we demonstrated, the net effect of the ECPR could be harmful.

If the rival is more efficient than the monopolist, then the monopolist's profit-maximizing strategy would generally¹⁵ be to cede production of the complementary component to the more efficient rival and to reap its monopoly profits through an appropriate access fee.¹⁶ This access fee could be either greater or less than the ECPR, depending on the shape of the demand curve for through service.

Thus, for this case the presence of the ECPR would allow production to shift to the more efficient producer. But the ECPR access fee would mean that consumers would continue to endure the inefficiencies of the artificially high price for through service. And the divergence of the ECPR from the monopolist's profit-maximizing access fee could imply either further distortion (if the ECPR is higher than the profit-maximizing fee) or a lessening of distortion (if the ECPR is lower).¹⁷

¹⁵ We discuss exceptions below in the text.

¹⁶ By ceding all production of the complementary component to the rival, the monopolist might be creating problems of vertical supplier-customer relationships, with the consequent problems of double marginalization, etc. But the monopolist's ability to self-supply the complementary component at its own marginal cost would put a limit on the extent to which the rival could attempt to exploit that position.

¹⁷ The discussion in this section thus indicates that a more complete "Williamson" type analysis should also include the possibility that a more efficient rival might enter, and the absence of the ECPR would

IV. The complementary components of the monopolist and the rival are imperfect substitutes

We now assume that the complementary components of the monopolist and the rival are imperfect substitutes; i.e., the monopolist and the rival compete in offering through service, but their service offerings are not identical. To continue with our telephone example, the rival's through service (e.g., long-distance service) might involve faster connections or a higher percentage of completed calls, but also an increased level of static on the line, as compared with the monopolist's long-distance service.

The introduction of imperfect substitutes immediately calls into question the meaning of any comparisons of production cost efficiency between the two components. Since the two components now have different attributes and satisfy (somewhat) different demands, comparisons of their unit costs have little or no meaning. It is rarely interesting or analytically worthwhile to compare the "unit" costs of an apple producer and an orange producer.

Even if the units of the two complementary components are somehow comparable, the analog of the ECPR's consequences for the perfect substitutes case is that the imposition of the ECPR to the rival's imperfect substitute would exclude a rival's production entirely when there was no customer with a willingness to pay for the rival's service such that the rival's price-less-costs margin could exceed the ECPR access fee. Unless the ECPR were based on a marginal-cost pricing rule (and thus in this case there were no customers of the rival's service whose willingness to pay would cover all relevant marginal costs), the exclusion of these "modest" willingness-to-pay customers by the ECPR access fee would not serve the goal of promoting production efficiency.¹⁸

If we move away from a production efficiency criterion, then an access fee might serve some other purpose—say, maximize the

mean that consumers would enjoy the full benefits of the lower price brought by the entrant.

monopolist's profits, or help solve a Ramsey pricing problem if inadequate revenues can be earned from the monopolist's bottleneck service customers. Only by chance would the ECPR access fee be the solution to either of these problems.

V. Economies of scale

In the presence of economies of scale in the production of the bottleneck service and/or the complementary component, the ECPR is again unlikely to provide a first-best pricing outcome.

A. *Ramsey pricing*

Suppose, contrary to our earlier assumption, that the monopolist is unable to earn sufficient revenue in the bottleneck market to cover its costs (e.g., because of economies of scale). In the absence of any other source of funds, the regulator must extract a contribution from the customers of through service. To maximize social welfare, the regulator must solve a Ramsey problem: select the set of prices for local service and through service that maximizes consumers' surplus while also covering the costs of those services. The resulting Ramsey price for through service would involve, in essence, an excise tax that is levied on through service. If the monopolist is the low cost producer of the complementary component, the monopolist "pays the excise tax to itself"; if the rival is the low cost producer, the rival pays the tax to the monopolist as an access fee. To insure optimality, the regulator would have to regulate directly the excise tax and the resulting price of through service. Only by chance would the ECPR access fee be identical to the Ramsey excise tax.¹⁹

B. *The monopolist may use the ECPR to exclude a more efficient rival*

There are at least two circumstances in which the monopolist's profit-maximizing strategy is to exclude the rival, even when the

¹⁹ See Laffont & Tirole, *supra* note 1; Armstrong & Doyle, *supra* note 1; and Armstrong & Vickers, *supra* note 1.

rival is more efficient at producing the complementary component, rather than cede production to the rival. In both instances, the monopolist would find it worthwhile to understate its own marginal costs of production of the complementary component and then impose a heightened ECPR on the rival.

In the first case, we now assume either that segment BC is a separate stand-alone market (as would be true for local railroad freight hauling) or that it is a complementary component for through service to (or from) points D, E, F, etc., that are served by other firms (but not by the original monopolist). We also depart from our assumption of constant returns to scale in the production of the complementary component and instead assume that there are economies of scale. If the monopolist can exclude the (more efficient) rival from offering through service in the ABC market, this could sufficiently deprive the rival of the benefits of scale so that the (less efficient) monopolist would also be the monopolist of the BC segment and reap monopoly profits from the stand-alone BC service or from the through service to the other points. To achieve this outcome, the monopolist could understate its marginal costs of production of the complementary component (BC service) and then employ the ECPR criterion to levy an exclusionary access fee vis-a-vis the rival.

As a second case, we alter our earlier assumption about the monopolist's behavior in the bottleneck market. We assume that the monopolist is constrained by regulation to earn zero excess profits in the bottleneck market. If, however, the regulator cannot observe the monopolist's costs perfectly, then the monopolist can increase its aggregate profits by claiming that some of its costs of production of the complementary component should be treated (for regulatory purposes) as costs of production of the bottleneck services.²⁰ To the extent that the monopolist succeeds in this "cre-

²⁰ This is a well-known possibility and was one of the major arguments for separating regulated monopoly local telephone service from other complementary services. See, for example, Roger G. Noll & Bruce M. Owen, *The Anticompetitive Uses of Regulation: United States v. AT&T*, in *THE ANTITRUST REVOLUTION: THE ROLE OF ECONOMICS* 328 (John E. Kwoka & Lawrence J. White eds., 1994); Timothy J. Brennan, *Why*
